A generalized Biot–Gassmann model for the acoustic properties of shaley sandstones

José M. Carcione, Boris Gurevich and Fabio Cavallini

Abstract
We obtain the wave velocities of clay-bearing sandstones as a function of clay content, porosity and frequency. Unlike previous theories, based simply on slowness and/or moduli averaging or two-phase models, we use a Biot-type three-phase theory that considers the existence of two solids (sand grains and clay particles) and a fluid. The theory, which is consistent with the critical porosity concept, uses three free parameters that determine the dependence of the dry-rock moduli of the sand and clay matrices as a function of porosity and clay content.

Testing of the model with laboratory data shows good agreement between predictions and measurements. In addition to a rock physics model that can be useful for petrophysical interpretation of wave velocities obtained from well logs and surface seismic data, the model provides the differential equation for computing synthetic seismograms in inhomogeneous media, from the seismic to the ultrasonic frequency bands.

Introduction
Successful interpretation of sonic logs and seismic data depends on a knowledge of the behaviour of wave propagation through rocks and geological units. In particular, sandstone reservoirs account for nearly 60% of oil reserves. In general, sandstones contain clay that considerably affects the seismic properties, such as compressional- and shear-wave velocities (Han, Nur and Morgan 1986). Previous attempts to model the effect of clay intrusions in sandstone assume empirical relationships (Tosaya and Nur 1982; Han et al. 1986) or a combination of empirical relationships and microstructural theories (Xu and White 1995; Goldberg and Gurevich 1998). While these models give reasonably good estimates of velocities from porosity and clay content, they are not always suitable for the calculation of synthetic seismograms, because they do not take dynamics into account.

Modelling the acoustic properties of shaley sandstones, that is, quantifying the variations of wave amplitudes and $V_p$ and $V_s$ versus porosity, clay content and...
frequency, is achieved in the framework of Biot’s theory of poroelasticity. This approach also provides the time-domain differential equations for calculation of synthetic seismograms in heterogeneous media.

For clay/sand mixtures, such an approach requires the consideration of a medium consisting of three phases: sand, clay and fluid. A three-phase Biot-type theory was recently developed by Leclaire, Cohen-Ténoudji and Aguirre-Puente (1994) for frozen porous media. This three-phase theory assumes that there is no direct contact between sand grains and ice, implying the existence of a water layer around the grains, isolating them from the ice. The model, which predicts three compressional waves and two shear waves, has recently been applied, with some minor modifications, to modelling the acoustic properties of permafrost (Carcione and Seriani 1998).

In this study, we replace ice by clay and include the terms responsible for the interaction between the sand grains (pure quartz grains) and the clay particles in the potential and kinetic energies. Lagrange’s equations provide the differential equations of motion, and a plane-wave analysis gives the wave velocities and attenuation factors of the different modes. The bulk and shear moduli of the sand and clay matrices versus porosity are obtained from a relationship proposed by Krief et al. (1990). This relationship introduces two empirical parameters that can be obtained by calibrating the model with real data. An additional parameter provides one more degree of freedom for adjusting the velocity–porosity curves (at constant clay content) to the data.

The present model is somewhat similar to that recently proposed by Goldberg and Gurevich (1998). An important difference, however, is associated with our three-phase approach. Indeed, Goldberg and Gurevich (1998) assumed that the medium is composed of two phases: solid and fluid. The solid matrix, in turn, is a composite material, made of sand grains and clay particles. The elastic moduli of the solid/fluid

![Figure 1. Interpenetrating sand (dark grey) and clay (light grey) matrices forming the composite skeleton of the shaley sandstone.](image-url)
mixture were derived using the Gassmann equation. However, the latter is valid only when the solid matrix is homogeneous (Brown and Korringa 1975). This implies that the sand and clay particles are mixed homogeneously, forming, in effect, composite grains, which in turn form the rock matrix. Our three-phase approach is free of such assumptions, but it also implies a particular topological configuration, namely the one where sand and clay form two continuous and interpenetrating solid matrices (see Fig. 1). As an example, we test the model on the published data set of Han et al. (1986) and Klimentos and McCann (1990).

Model for clay-bearing sediments

The theory developed by Leclaire et al. (1994) explicitly takes into account the presence of three phases: solid substrate, ice and water. Here, we replace the ice with clay and include the contributions to the potential and kinetic energies due to the contact between the sand grains and the clay. In analogy with their notation, \( \nu = 1, 2, 3 \) denote sand, water and clay, respectively.

Following Leclaire et al. (1994), the equation of motion can be written in matrix form as

\[
\mathbf{R} \text{ grad div } \mathbf{u} - \mathbf{\mu} \text{ curl curl } \mathbf{u} = \rho \ddot{\mathbf{u}} + \mathbf{A} \dot{\mathbf{u}},
\]

where \( \mathbf{u} \) is the displacement field,

\[
\mathbf{R} = \begin{pmatrix}
R_{11} & R_{12} & R_{13} \\
R_{12} & R_{22} & R_{23} \\
R_{13} & R_{23} & R_{33}
\end{pmatrix}
\quad \text{and} \quad
\mathbf{\mu} = \begin{pmatrix}
\mu_{11} & 0 & \mu_{13} \\
0 & 0 & 0 \\
\mu_{13} & 0 & \mu_{33}
\end{pmatrix}
\]

are the bulk and shear stiffness matrices, respectively, while

\[
\mathbf{\rho} = \begin{pmatrix}
\rho_{11} & \rho_{12} & \rho_{13} \\
\rho_{12} & \rho_{22} & \rho_{23} \\
\rho_{13} & \rho_{23} & \rho_{33}
\end{pmatrix}
\]

is the mass density matrix, and

\[
\mathbf{A} = \begin{pmatrix}
b_{11} & -b_{11} & 0 \\
-b_{11} & b_{11} + b_{33} & -b_{33} \\
0 & -b_{33} & b_{33}
\end{pmatrix}
\]

is the friction matrix, where the parameter \( b_{13} \), describing the interaction between the sand and clay matrices, has been assumed equal to zero. The fact that there is a frictionless connection between the two constituents can be interpreted as the sand and clay frames being welded (or bonded). There is an interchange of kinetic energy (described by \( \rho_{13} \)) and potential energy (described by \( R_{13} \) and \( \mu_{13} \)) at the contact points, but no dissipation.
A dot above a variable denotes time differentiation. All the parameters with the subscript (13) describe the interaction between the two solid components. The elements of these matrices are obtained with the use of Lagrange’s equations (Leclaire et al. 1994).

Appendix A summarizes the meaning of the different parameters, and Appendix B describes the form of the potential and kinetic energies. The porosity dependence of the sand and clay matrices is consistent with the concept of critical porosity, since the moduli should vanish above a certain value of the porosity (usually from 0.4 to 0.5). This dependence is determined by the empirical coefficients $A_s$ and $A_c$ (see equation (1)). This relationship was suggested by Krief et al. (1990) and applied to sand/clay mixtures by Goldberg and Gurevich (1998). Moreover, in some rocks there is an abrupt change of rock matrix properties with the addition of a small amount of clay, attributed to softening of cements, clay swelling and surface effects, i.e. the wave velocities decrease significantly when the clay content increases from 0 to a few percent (Goldberg and Gurevich 1998). In order to model this effect, we multiply the shear modulus of the sand matrix by a factor depending on the empirical coefficient $a$ (see equation (2): this factor tends to 1 when $a \to \infty$). Then, the bulk and shear moduli of the sand and clay matrices are assumed to satisfy the equations

$$K_{sm} = K_s \phi_s (1 - \phi)^{A_s/(1 - \phi)}, \quad K_{cm} = K_c \phi_c (1 - \phi)^{A_c/(1 - \phi)}$$

and

$$\mu_{sm} = \exp \left\{ -[(1 - C)C]^2 \right\} K_{sm} \mu_s/K_s, \quad \mu_{cm} = K_{cm} \mu_c/K_c, \quad (2)$$

respectively. Note that $\phi + \phi_s + \phi_c = 1$ and $C = \phi_c/(\phi_c + \phi_s)$, whence $\phi_c$ and $\phi_s$ can be expressed in terms of porosity $\phi$ and clay content $C$, which prove to be the only independent variables of the model. Krief et al. (1990) set the parameters $A_s$ and $A_c$ at 3 regardless of the lithology, and Goldberg and Gurevich (1998) obtained values between 2 and 4. On the other hand, since $C(1 - C) < 1$, the exponential in (2) takes values between 0.166 (for $a = 0$) and 1 (for $a = \infty$). We found that reasonable values of parameter $a$ are in the range $[0,1]$.

The expressions (B6) for the density components, given in Appendix B, include the interaction between sand grains and clay particles, assuming that the grains flow through the clay matrix (as described by the tortuosity $a_{13}$) and that the clay particles flow through the sand skeleton (as described by $a_{31}$). As is well known, the tortuosity is related to the difference between the microvelocity and macrovelocity fields. If they are similar (i.e. for relatively rigid materials such as solids), the tortuosities equal 1, and these contributions vanish. However, these terms do contribute to the kinetic energy when the sand and clay matrices are unconsolidated or relatively unconsolidated, for which the tortuosities are greater than 1. As in Biot theory, we neglect the solid contributions related to the interaction with the saturating fluid.

If the properties of the clay equal those of the sand grains, then $u_3 = u_1$, $\theta_3 = \theta_1$, $d_3 = d_1$, and we obtain Biot’s potential and kinetic energies, with the corresponding coefficients (see Appendix A), depending only on $\phi_s + \phi_c$. Moreover, when $\phi \to 1$, © 2000 European Association of Geoscientists & Engineers, Geophysical Prospecting, 48, 539–557
the compressional-wave velocity tends to the wave velocity in the fluid, and the shear-wave velocity vanishes.

The reference frequency \( f_c \), which determines the validity of the theory, \( f \ll f_c \), is given by

\[
f_c = \frac{\phi \eta_k}{2 \pi T \rho_k \kappa},
\]

where we assume that the permeability is \( \kappa = \phi_s \kappa_s + \phi_c \kappa_c \) (see Appendix B) and that the tortuosity is obtained from \( 1/T \approx (1 - C)/a_{21} + C/a_{23} \).

The three compressional-wave velocities of the three-phase porous medium are given by

\[
V_{Pm} = [\text{Re}(\sqrt{\Lambda_m})]^{-1}, \quad m = 1, 2, 3,
\]

where \( \text{Re} \) denotes the real part, and \( \Lambda_m \) are obtained from the generalized characteristic equation \( \det[\Lambda \mathbf{R} - \hat{\mathbf{p}}] = 0 \), which yields

\[
\Lambda^3 \det[\mathbf{R}] - \Lambda^2 \text{tr}[\mathbf{R} \hat{\mathbf{p}}] + \Lambda \text{tr}[\mathbf{R} \hat{\mathbf{p}}] - \det \hat{\mathbf{p}} = 0,
\]

where \( \text{tr} \) denotes the trace, the overbar denotes the cofactor matrix (e.g. Fedorov 1968), and the effective density matrix,

\[
\hat{\mathbf{p}} = \mathbf{p} - i \Lambda/\omega,
\]

is defined in the frequency domain.

Likewise, the two shear-wave velocities \( V_{Sm} \) are given by

\[
V_{Sm} = [\text{Re}(\sqrt{\Omega_m})]^{-1}, \quad m = 1, 2,
\]

where \( \Omega_m \) are the complex solutions of the equation

\[
\Omega^2 a' - \Omega b' + \det(\hat{\mathbf{p}}) = 0,
\]

with \( a' = \text{tr}[\mathbf{M} \hat{\mathbf{p}}] \) and \( b' = \text{tr}[\mathbf{M} \hat{\mathbf{p}}] \).

Following Dutta and Ode (1983), the magnitudes of the attenuation vectors (in dB) are given by

\[
\alpha_{Pm} = 17.372 \pi \frac{\text{Im}(\sqrt{\Lambda_m})}{\text{Re}(\sqrt{\Lambda_m})}, \quad m = 1, 2, 3,
\]

and

\[
\alpha_{Sm} = 17.372 \pi \frac{\text{Im}(\sqrt{\Omega_m})}{\text{Re}(\sqrt{\Omega_m})}, \quad m = 1, 2.
\]

Examples

We calibrate the model with the data sets published by Han et al. (1986) and Klimentos and McCann (1990), obtained at a confining pressure of 40 MPa. Han

Figure 2. Velocities of compressional (a) and shear (b) fast waves versus porosity $\phi$ for different values of clay content $C$: black: $C = 0\%$; red: $C = 10\%$; green: $C = 20\%$; blue: $C = 30\%$, and light blue: $C = 40\%$. The experimental points correspond to the data published by Han et al. (1986). In this case, black, red, green, blue and light blue correspond to $C$ values in the ranges $[C, C + 5\%]$, $C = 0, \ldots, 40\%$. The frequency is 5 kHz.
et al. (1986) provide ultrasonic measurements of $V_p$ and $V_s$ for 75 sandstone samples with porosities ranging from 2 to 30% and a volume clay content from 0 to 50%. One feature of this data set is that a small amount of clay significantly softens the rock moduli, leading to reduced velocities. Table 1 shows the properties of the different constituents, and the prediction of the theory against the measurements obtained by Han et al. (1986) is shown in Figs 2a and b, where $A_e = A_c = 2$ and $a = 0.5$ (see equations (1) and (2)). The reference frequency (3) is $f_c = 84, 140, 18$ and $25$ kHz for $(\phi, C) = (0.1, 0), (0.1,0.4), (0.3,0)$ and $(0.3,0.4)$, respectively. Since the theory is valid below these reference frequencies, we assume a frequency of 5 KHz to fit the experimental data. Strictly speaking, this is not correct since the data have been acquired at ultrasonic frequencies of the order of hundreds of kHz. However, it is well known that Biot-type dissipation mechanisms alone do not account for the level of attenuation observed in rocks (Dvorkin, Nolen-Hoeksema and Nur 1994). A correct
description of this phenomenon would require the generalization of the different stiffness moduli to relaxation functions (Biot 1962). However, this fact reflects the robustness of the model for this particular example. Figure 2 shows the compressional- and shear-wave velocities versus porosity, where each curve corresponds to a different value of the clay content $C$. The root-mean-square deviation computed for all samples, apart from five outliers for P-waves and seven outliers for S-waves, is 93 m/s for the P-wave velocity and 100 m/s for the S-wave velocity. The match between theoretical and experimental data is quite good taking into account the fact that we used just two fitting parameters and did not use a rigorous parameter estimation algorithm. The values for $A_s$ and $A_c$ were chosen to obtain a reasonable fit of the data. The fact that $A_s = A_c$ is a satisfactory choice indicates the flexibility of the model in this case. In order to obtain a better agreement between theory and experiment, an inversion procedure, like that presented by Goldberg and Gurevich (1998), should be used. On the other hand, Fig. 3 represents the same velocities versus clay content $C$ for porosities ranging from zero to 40%. The rapid decrease in wave velocity at low clay content is evident.

Figure 4 shows the compressional-wave velocity compared with the experimental points obtained by Klimentos and McCann (1990). In this case $a = 1$, since the softening of the rock moduli by clay is less pronounced than in the previous case. This data set was obtained at a confining pressure of 40 MPa, which, according to the authors, is equivalent to a depth of burial of about 1.5 km. For an average sediment density of 2300 kg/m$^3$, this requires a pore pressure of 19 MPa, and therefore an overpressure of approximately 4.5 MPa. In fact, the porosities are higher than those expected at 1.5 km depth. Pore pressure, together with the confining pressure, determines the differential pressure which, in turn, determines the dry-rock bulk
An acoustic model for shaley sandstones

moduli and porosity (Zimmerman, Somerton and King 1986). Hence, the pressure dependence is mainly contained in (1) and (2) through the porosity \( \phi \) and the parameters \( A_s \), \( A_c \) and \( a \). Second-order effects can be due to the dependence on pressure and temperature of the fluid properties (Batzle and Wang 1992).

The attenuations (6) and (7) for the fast waves in the seismic band are shown in Fig. 5. In general, the higher the porosity the higher the dissipation. For completeness, Fig. 6 shows the phase velocities, computed using (4) and (5), and attenuations, computed using (6) and (7), of the slow compressional modes and the slow shear mode for a frequency of 25 Hz. Note that the attenuations of the slow modes are much higher than the attenuations of the fast modes, as expected. Modes have been numbered in order of decreasing phase speed.

It is important to note that the main advantage of the present model is not the accuracy of the prediction (empirical relationships may perform equally well), but the fact that it is a model based on physical grounds and is potentially useful for the inversion of rock properties and the computation of synthetic seismograms.

Conclusions

We have developed a new velocity-porosity-clay model that can be used for inversion applications such as sonic-log interpretation, lithological inversion of seismic data, AVO

Figure 5. Compressional (a) and shear (b) attenuations in dB versus porosity for different values of clay content, which varies in steps of 0.1 from 0 to 1. The frequency is 25 Hz. Curves with higher peaks correspond to lower clay content.
The model is based on a Biot-type formulation of the equation of motion, and therefore the number of free parameters is limited to a minimum. In principle, three parameters are used to obtain the bulk and shear moduli of the sand and clay matrices versus porosity and clay content. In the present study, two parameters were enough to fit the experimental data. Since the model is based on a Biot formulation, additional compressional and shear waves are predicted by the theory. For completeness, the characteristics (phase velocity and attenuation) of these modes are briefly outlined. Besides the inversion applications mentioned above, the formulation provides the differential equations for computing synthetic seismograms in inhomogeneous porous media.

Energies and friction coefficients

In their model of a frozen porous medium, Leclaire et al. (1994) assumed that there is no direct mechanical contact between the solid and ice, because they are separated by water. The model is generalized here in order to include the interaction between the sand grains and the clay, which corresponds to ice, and the coefficients of the dissipation potential. Following their notation, \( u_n \), for \( n = 1, 2, 3 \), denote the displacement vectors of sand, water and clay, respectively.

**B1. Potential energy density**

The total potential energy of the system can be expressed as

\[
E_P = \mu_{11} d_1^2 + \frac{1}{2} K_1 \theta_1^2 + C_{12} \theta_1 \theta_2 + \frac{1}{2} K_2 \theta_2^2 + C_{23} \theta_2 \theta_3 + \frac{1}{2} K_3 \theta_3^2 + \mu_{33} d_3^2
\]

\[
+ C_{13} \theta_1 \theta_3,
\]

where \( \theta_n \) and \( d_n \) are the invariants of the strain tensor, called dilatations and deviators, while \( K_n \) and \( \mu_{n,n'} \) are, respectively, the bulk and shear moduli of the effective phases.

All the parameters, except \( C_{13} \), are as given by Leclaire et al. (1994), although sand/clay interactions are now taken into account. In order to calculate \( C_{13} \), we generalize the elastic moduli obtained for the two-phase Biot’s theory. For a medium with a proportion of sand \( \phi_s \) and a porosity \( \phi \), the elastic moduli are

\[
K_1 = (1 - c_1)^2 \phi_s^2 K_a,
\]

\[
C_{12} = (1 - c_1) \phi_s \phi K_a, \tag{B1}
\]

\[
K_2 = \phi^2 K_a,
\]

where

\[
K_a = \left[ (1 - c_1) \frac{\phi_s}{K_s} + \frac{\phi}{K_f} \right]^{-1}, \quad c_1 = \frac{K_{sm}}{\phi_s K_s}.
\]

Here \( K_s \) and \( K_f \) are the solid and fluid bulk moduli, \( K_a \) is the average bulk modulus, \( K_{sm} \) is the solid matrix bulk modulus, and \( c_1 \) is the bulk consolidation coefficient, such that \( c_1 = 0 \) for a suspension of solid grains in a fluid, and \( c_1 = 1 \) for a situation where

\[
\rho_c, \quad \text{clay density; see Table 1;}
\]

\[
\rho_f, \quad \text{fluid density; see Table 1;}
\]

\[
\rho_s, \quad \text{sand density; see Table 1;}
\]

\[
\rho_{\nu,\nu'}, \quad \text{generalized mass coefficients (see Appendix B.2);}
\]

\[
\theta_\nu, \quad \text{dilatation (}\nu = 1, 2, 3\text{).}
\]
the grains form a monolithic block. Note that equations (B1) correspond to an effective solid porosity \( \phi_s' = (1 - c_1)\phi_s \). If we replace the fluid by clay, the equations should read

\[
K_1 = \phi_s'^2 K_a, \\
C_{13} = \phi_s' \phi_c' K_a, \\
K_3 = \phi_c'^2 K_a,
\]

where

\[
K_a = \left[ \frac{\phi_s' + \phi_c'}{K_s + K_c} \right]^{-1}, \quad \phi_c' = (1 - c_3)\phi_c, \quad c_3 = \frac{K_{cm}}{\phi_c K_c}.
\]

Here \( c_3 \) is the bulk consolidation coefficient of the clay matrix, with bulk modulus \( K_{cm} \). For the three-phase system, the generalization of \( K_a \) to \( K_{av} \) gives

\[
K_1 = (1 - c_1)^2 \phi_s'^2 K_{av}, \\
C_{13} = (1 - c_1)\phi_s (1 - c_3)\phi_c K_{av}, \\
K_3 = (1 - c_3)^2 \phi_c'^2 K_{av}, \\
K_{av} = \left[ \phi_s' K_s + \phi_c' K_c + \frac{\phi}{K_f} \right]^{-1}.
\]

\[B.2\text{ Kinetic energy density}\]

The kinetic energy is a function of the local velocities \( \dot{\mathbf{u}}_1, \dot{\mathbf{u}}_2 \) and \( \dot{\mathbf{u}}_3 \), where the dot denotes time differentiation. Generalizing Leclaire et al.’s (1994) kinetic energy, we get

\[
E_K = \frac{1}{2} \rho_{11} \| \dot{\mathbf{u}}_1 \|^2 + \frac{1}{2} \rho_{22} \| \dot{\mathbf{u}}_2 \|^2 + \frac{1}{2} \rho_{33} \| \dot{\mathbf{u}}_3 \|^2 \\
+ \rho_{12} \dot{\mathbf{u}}_1 \cdot \dot{\mathbf{u}}_2 + \rho_{23} \dot{\mathbf{u}}_2 \cdot \dot{\mathbf{u}}_3 + \rho_{13} \dot{\mathbf{u}}_1 \cdot \dot{\mathbf{u}}_3,
\]

where, for simplicity, we omit the tilde above the density components.

We now want to determine the induced mass tensor \( \rho_{ij} \). To this purpose we first deduce an expression for the kinetic energy through a microstructural argument and then compare the result with (B2). Let us define the macroscopic velocities

\[
\mathbf{w}_1 = \phi (\mathbf{u}_2 - \mathbf{u}_1) \quad \text{and} \quad \mathbf{w}_3 = \phi (\mathbf{u}_2 - \mathbf{u}_3),
\]
which describe the flow of water with respect to sand and clay, respectively. Likewise,

\[ q = \phi_1(u_3 - u_1) \quad \text{and} \quad r = \phi_3(u_1 - u_3) \]

denote the macroscopic velocities characterizing the movement of clay relative to the sand grains and vice versa, respectively. Since the relative flows are assumed to be of laminar type, the microscopic velocities can be expressed as

\[ v_1 = \alpha_1 w_1 \quad \text{and} \quad v_3 = \alpha_3 w_3 \]

and

\[ s = \beta_1 q \quad \text{and} \quad t = \beta_3 r, \]

where \( \alpha_1 \) and \( \alpha_3 \) are the fluid/sand and fluid/clay matrix coefficients, and \( \beta_1 \) and \( \beta_3 \) are the clay/sand and sand/clay matrix coefficients, respectively.

The total kinetic energy is given by the expression,

\[
E_K = \frac{1}{2} \rho_f \int \int \int_{\Omega_f} ||\ddot{u}_1 + v_1||^2 \, d\Omega + \frac{1}{2} \rho_f \int \int \int_{\Omega_f} ||\ddot{u}_3 + v_3||^2 \, d\Omega + \\
\frac{1}{2} \rho_c \int \int \int_{\Omega_c} ||\ddot{u}_1 + s||^2 \, d\Omega + \frac{1}{2} \rho_s \int \int \int_{\Omega_s} ||\ddot{u}_3 + t||^2 \, d\Omega - \frac{1}{2} \rho_f \phi \|\dddot{u}_2\|^2, 
\]

where \( \Omega_f, \Omega_c \) and \( \Omega_s \) are the volumes of fluid, clay and sand grains, respectively. The term \( (1/2)\rho_f \phi \|\dddot{u}_2\|^2 \) is subtracted since the contribution of the fluid must be considered only once in the kinetic energy.

Following Leclaire et al. (1994), we define

\[
m_{ij}^{(l)} = \rho_f \int \int \int_{\Omega^{(l)}} \sum_{k} \phi_{ki}^{(l)} \phi_{kj}^{(l)} \, d\Omega, \quad l=1,3, 
\]

where \( \Omega^{(1)} = \Omega_c, \Omega^{(3)} = \Omega_s \), and

\[
n_{ij}^{(1)} = \rho_c \int \int \int_{\Omega_c} \sum_{k} \beta_{ki}^{(1)} \beta_{kj}^{(1)} \, d\Omega, \quad n_{ij}^{(3)} = \rho_s \int \int \int_{\Omega_s} \sum_{k} \beta_{ki}^{(3)} \beta_{kj}^{(3)} \, d\Omega. 
\]

Assuming statistical isotropy, we obtain \( m_{ij}^{(l)} = m_l \delta_{ij} \) and \( n_{ij}^{(l)} = n_l \delta_{ij} \); therefore (B3) simplifies to

\[
E_K = \frac{1}{2} \rho_2 \|\dddot{u}_1\|^2 + \rho_f \dddot{u}_1 \cdot \dddot{w}_1 + \frac{1}{2} m_1 \|\dddot{w}_1\|^2 + \frac{1}{2} \rho_2 \|\dddot{u}_3\|^2 + \rho_f \dddot{u}_3 \cdot \dddot{w}_3 + \\
+ \frac{1}{2} m_3 \|\dddot{w}_3\|^2 + \frac{1}{2} \rho_3 \|\dddot{u}_1\|^2 + \rho_c \dddot{u}_1 \cdot \dddot{q} + \frac{1}{2} n_1 \|\dddot{q}\|^2 + \frac{1}{2} \rho_1 \|\dddot{u}_3\|^2 + \\
+ \rho_c \dddot{u}_3 \cdot \dddot{r} + \frac{1}{2} n_3 \|\dddot{r}\|^2 - \frac{1}{2} \rho_2 \|\dddot{u}_2\|^2, 
\]

where

\[
\rho_1 = \rho_c \phi_s, \quad \rho_2 = \rho_f \phi, \quad \rho_3 = \rho_c \phi_c. 
\]
Finally, expressing the kinetic energy as a function of $\mathbf{u}_1$, $\mathbf{u}_2$ and $\mathbf{u}_3$, we get

$$E_K = \frac{1}{2}(n_3\phi_s^2 - \rho_2 + m_1\phi^2 - \rho_3 + n_1\phi_c^2) \parallel \mathbf{u}_1 \parallel^2$$

$$+ \frac{1}{2}(m_1\phi^2 + m_3\phi^2 - \rho_2) \parallel \mathbf{u}_2 \parallel^2$$

$$+ \frac{1}{2}(n_1\phi_c^2 - \rho_2 + m_3\phi^2 - \rho_1 + n_3\phi_s^2) \parallel \mathbf{u}_3 \parallel^2$$

$$+ (\rho_2 - m_1\phi^2)\mathbf{u}_1 \cdot \mathbf{u}_2 + (\rho_2 - m_3\phi^2)\mathbf{u}_2 \cdot \mathbf{u}_3$$

$$+ (\rho_1 - n_3\phi_s^2 + \rho_3 - n_1\phi_c^2)\mathbf{u}_1 \cdot \mathbf{u}_3.$$  \hspace{1cm} (B5)

The generalized mass densities $\rho_{ij}$ are obtained from the identification of the coefficients of expression (B5) with those of (B2). This gives

$$\rho_{11} = \rho_s\phi_s a_{13} + (a_{21} - 1)\rho_t\phi + (a_{31} - 1)\rho_c\phi_c,$$

$$\rho_{22} = (a_{21} + a_{23} - 1)\rho_t\phi,$$

$$\rho_{33} = \rho_c\phi_c a_{31} + (a_{23} - 1)\rho_t\phi + (a_{13} - 1)\rho_s\phi_s,$$

$$\rho_{12} = -(a_{21} - 1)\rho_t\phi,$$

$$\rho_{23} = -(a_{23} - 1)\rho_t\phi,$$

$$\rho_{13} = -(a_{13} - 1)\rho_s\phi_s - (a_{31} - 1)\rho_c\phi_c,$$  \hspace{1cm} (B6)

where

$$a_{21} = \frac{m_1\phi}{\rho_t}, \quad a_{23} = \frac{m_3\phi}{\rho_t}$$

and

$$a_{13} = \frac{n_3\phi_s}{\rho_s}, \quad a_{31} = \frac{n_1\phi_c}{\rho_c}$$

are the tortuosity parameters.

When there is no relative motion between the three phases, the following relationship holds

$$\rho = \rho_{11} + \rho_{22} + \rho_{33} + 2(\rho_{12} + \rho_{23} + \rho_{13}) = \rho_1 + \rho_2 + \rho_3,$$

whence $\rho$ may be viewed as the effective mass density.

Following Berryman (1980), we express the tortuosity parameters as

$$a_{21} = \frac{\phi_t}{\phi} r_{12} + 1, \quad a_{23} = \frac{\phi_t}{\phi} r_{23} + 1, \quad a_{13} = \frac{\phi_c}{\phi_s} r_{13} + 1, \quad a_{31} = \frac{\phi_s}{\phi_c} r_{31} + 1,$$
where \( r_{\nu \nu'} \) characterize the geometrical features of the pores (\( r_{\nu \nu} = 1/2 \) for spheres). Observe that, for instance, \( a_{21} \to 1 \) for \( \phi \to 1 \) and that \( a_{21} \to \infty \) for \( \phi \to 0 \), as expected (Berryman 1980).

B.3 Friction coefficients

In order to obtain the viscous flow resistance coefficients \( b_{11} \) and \( b_{33} \), we first consider the idealized situation when the solid part can be modelled as a dilute concentration of sand and clay spherical particles in the fluid. This situation is realized in the high-porosity limit (\( \phi \to 1 \)). Since the concentration is dilute, each particle can be considered independently from the others. The viscous resistance force for a single sphere of radius \( R \) moving in a flow of average velocity \( v \) and a fluid viscosity \( \eta_f \) obeys Stokes’s law,

\[
F = 6 \pi \eta_f v R.
\]

Suppose that in a unit volume we have \( n_\nu \) particles of radius \( R_\nu \), where \( \nu = 1 \) (sand grains) or \( 3 \) (clay particles). Then, the viscous resistance to the flow by particles of type \( \nu \) can be written as

\[
F_\nu = 6 \pi \eta_f v n_\nu R_\nu. \tag{B7}
\]

The density numbers \( n_\nu \) can be thought of as the total volume of the particles of type \( \nu \) divided by the volume of a single particle,

\[
n_\nu = \frac{\phi_\nu}{\frac{4}{3} \pi R_\nu^3}. \tag{B8}
\]

Substitution of (B8) into (B7) yields

\[
F_\nu = \frac{9}{2} \eta_f \phi_\nu R_\nu^{-2},
\]

or, for the viscous resistance coefficient,

\[
b_{\nu \nu} = F_\nu \frac{\phi^2}{\phi_\nu} = \frac{9}{2} \eta_f \phi^2 \phi_\nu R_\nu^{-2}. \tag{B9}
\]

Note that the quantity

\[
\kappa_\nu = \frac{2}{9} \frac{R_\nu^2}{\phi_\nu}
\]

can be thought of as a partial permeability of the matrix formed by particles of type \( \nu \). Hence

\[
b_{\nu \nu} = \eta_f \phi^2 \kappa_\nu^{-1}.
\]

© 2000 European Association of Geoscientists & Engineers, Geophysical Prospecting, 48, 539–557
Equation (B9) provides an explicit expression for the resistance coefficients $b_{11}$ and $b_{33}$ in the high-porosity limit. At lower porosities it is customary to divide the expression for permeability by an empirical factor $10(1 - \phi)/\phi^3$, which yields permeability values consistent with the Kozeny–Carman empirical relationship (Berryman 1995). Then, $\kappa_s$ and $\kappa_c$ are equal to $\kappa_1$ and $\kappa_3$ divided by that factor. We thus write

$$b_{\nu\nu} = 45 \eta_l R_{\nu}^{-2} \phi^{-1}(1 - \phi) \phi,$$

or

$$b_{11} = 45 \eta_l R_s^{-2} \phi^{-1}(1 - \phi)^2(1 - C),$$

$$b_{33} = 45 \eta_l R_c^{-2} \phi^{-1}(1 - \phi)^2 C,$$

where $R_s$ and $R_c$ denote the average radii of sand and clay particles, respectively.
