Elastic surface waves in crystals – Part 2: Cross-check of two full-wave numerical modeling methods

Dimitri Komatitsch a,1, José M. Carcione b, Fabio Cavallini b, Nathalie Favretto-Cristini c,*

Abstract

We obtain the full-wave solution for the wave propagation at the surface of anisotropic media using two spectral numerical modeling algorithms. The simulations focus on media of cubic and hexagonal symmetries, for which the physics has been reviewed and clarified in a companion paper. Even in the case of homogeneous media, the solution requires the use of numerical methods because the analytical Green's function cannot be obtained in the whole space. The algorithms proposed here allow for a general material variability and the description of arbitrary crystal symmetry at each grid point of the numerical mesh. They are based on high-order spectral approximations of the wave field for computing the spatial derivatives. We test the algorithms by comparison to the analytical solution and obtain the wave field at different faces (stress-free surfaces) of apatite, zinc and copper. Finally, we perform simulations in heterogeneous media, where no analytical solution exists in general, showing that the modeling algorithms can handle large impedance variations at the interface.

1. Introduction

The problem of surface acoustic wave (SAW) propagation in anisotropic media has been studied for many decades. Nevertheless, anisotropy induces great difficulties in analytically and explicitly studying wave propagation because the anisotropic behavior of the medium considerably modifies the existence and the structure of the SAW that propagates at the free surface of the medium (see a companion paper [1] for a detailed review). Few problems in elastodynamics have a closed-form analytical solution and some can be investigated with semi-analytical methods, but often one cannot be sure if these methods give reliable solutions. Being able to accurately simulate wave propagation numerically is therefore essential in a wide range of fields, including ultrasonics, earthquake seismology and seismic prospecting. The emergence of ultrasonic techniques for nondestructive evaluation has provided a strong impulse to the study of wave propagation and its numerical simulation [2–8]. Ultrasonic theory and numerical modeling is applied to the detection of flaws and micro-cracks, inhomogeneous stress field evaluation, and the characterization of effective mechanical properties of fibers and composites with imperfect interface bonding. These systems generally possess anisotropic properties, described, in their most general form, by 21 elastic coefficients and by the mass density of the material. Numerical simulations therefore become an attractive method to describe the propagation of SAWs generated by a point source at a free surface that can be different from a symmetry plane of a given anisotropic medium and for which no analytical solution can be derived.

In the following sections we use two full-wave numerical methods to solve the problem without any approximation regarding the type of symmetry or the orientation of the free surface. The methods are highly accurate because they are based on spectral representations of the wave field. We present some examples in hexagonal and cubic media, validation benchmarks against the analytical solution in known cases, and snapshots of propagation in more complex heterogeneous media.

2. Equation of motion

In a heterogeneous elastic, anisotropic medium, the linear wave equation may be written as

$$\rho \ddot{u} = V \cdot \sigma + f,$$

$$\sigma = C : \varepsilon,$$

$$\varepsilon = \frac{1}{2} [V u + (V u)^T].$$

(1)
where \( \mathbf{u} \) denotes the displacement vector, \( \mathbf{a} \) the symmetric, second-order stress tensor, \( \mathbf{e} \) the symmetric, second-order strain tensor, \( \mathbf{C} \) the fourth-order stiffness tensor, \( \rho \) the density, and \( \mathbf{f} \) an external source force. A dot over a symbol denotes time differentiation, a colon denotes the tensor product, and a superscript \( \top \) denotes the transpose.

In the case of a fully anisotropic medium, the 3-D stiffness tensor \( \mathbf{C} \) has 21 independent components. In 2-D, the number of independent components reduces to 6. Using the reduced Voigt notation \([9]\), Hooke's law may be written in the form

\[
\begin{bmatrix}
\sigma_{xx} \\
\sigma_{yy} \\
\sigma_{zz} \\
\sigma_{xz} \\
\sigma_{zy} \\
\sigma_{xy}
\end{bmatrix}
= \begin{bmatrix}
c_{11} & c_{12} & c_{13} & c_{14} & c_{15} & c_{16} \\
c_{21} & c_{22} & c_{23} & c_{24} & c_{25} & c_{26} \\
c_{31} & c_{32} & c_{33} & c_{34} & c_{35} & c_{36} \\
c_{41} & c_{42} & c_{43} & c_{44} & c_{45} & c_{46} \\
c_{51} & c_{52} & c_{53} & c_{54} & c_{55} & c_{56} \\
c_{61} & c_{62} & c_{63} & c_{64} & c_{65} & c_{66}
\end{bmatrix}
\begin{bmatrix}
\varepsilon_{xx} \\
\varepsilon_{yy} \\
\varepsilon_{zz} \\
\varepsilon_{xz} \\
\varepsilon_{zy} \\
\varepsilon_{xy}
\end{bmatrix}.
\]

(2)

Using this reduced notation, the stiffness matrix remains symmetric, i.e., \( c_{ij} = c_{ji} \). The isotropic case is obtained by letting \( c_{11} = c_{22} = c_{33} = \lambda + 2\mu, c_{12} = c_{13} = c_{23} = \lambda \) and \( c_{44} = c_{55} = c_{66} = \mu \), where \( \lambda \) and \( \mu \) are the two Lamé parameters; all other coefficients are then equal to zero.

In the case of a medium with free surfaces, e.g., the edges of a crystal, or the surface of the Earth, the boundary condition is zero traction at the surface: \( \mathbf{a} \cdot \mathbf{n} = 0 \), where \( \mathbf{n} \) is the unit outward normal vector. The reader is referred for instance to Crampin et al. \([10]\), Thomsen \([11]\), Helbig \([9]\) or Carcione \([12]\) for further details on wave propagation in anisotropic media.

### 3. Time-domain modeling methods

We propose algorithms to simulate surface waves in a material with arbitrary symmetry. The computations are based on two different numerical techniques, namely, the Fourier-Chebyshev pseudospectral method (PSM) \([13,14,12]\) and the spectral finite-element method (SEM) \([15–20]\). The first is based on global differential operators in which the field is expanded in terms of Fourier and Chebyshev polynomials, while the second is an extension of the finite-element method that uses Legendre polynomials as interpolating functions. Both methods have spectral accuracy up to approximately the Nyquist wavenumber of the mesh. One of the aims of this work is to provide reliable techniques to compute numerical solutions in, e.g., crystals, metals and minerals for which analytical solutions do not exist. The proposed algorithms can obtain solutions for general heterogeneous media because the space is discretized on a mesh whose grid points can have varying values of the elastic properties, i.e., the medium can be inhomogeneous.

#### 3.1. The pseudospectral method

The implementation of the pseudospectral method to simulate wave propagation in 2D and 3D unbounded anisotropic media is given in Carcione et al. \([21,22]\), respectively. The method including a free surface was first introduced by Kosloff et al. \([23]\) for the 2D isotropic-elastic case. For computing spatial derivatives, the scheme is based on the Fourier and Chebyshev differential operators in the horizontal and vertical directions, respectively. These operators have infinite accuracy (within machine precision) up to two points per wavelength (the Nyquist wavenumber) and \( \pi \) points per wavelength, respectively.

This modeling technique has been extended to the 3D anisotropic-elastic case by Tessmer \([13]\) and to the 3D isotropic-anelastic case by Carcione et al. \([24]\). The first algorithm is used here to model surface waves. For completeness and ease in programming, we explicitly outline the equation of motion and the complete boundary treatment used in the calculations. The particle-velocity/stress formulation is

\[
\dot{\mathbf{v}} = \mathbf{H} \cdot \mathbf{v} + \mathbf{f},
\]

(3)

where

\[
\mathbf{v} = (v^x, v^y, v^z, q^x, q^y, q^z)^\top \equiv (v_x, v_y, v_z; \sigma_{xx}, \sigma_{yy}, \sigma_{zz}, \sigma_{xz}, \sigma_{zy})^\top
\]

(4)

and

\[
\rho \mathbf{f} = (f_x, f_y, f_z, 0, 0, 0, 0, 0, 0)^\top
\]

(5)

are the particle-velocity/stress and body-force vectors (\( \mathbf{v} = \mathbf{u} \)).

\[
\mathbf{H} = \begin{pmatrix}
\mathbf{0}_6 \\
\mathbf{C} \cdot \nabla
\end{pmatrix} \rho^{-1} \nabla
\]

(6)

with

\[
\nabla = \begin{pmatrix}
\partial_x & 0 & 0 & 0 & \partial_y & 0 \\
0 & \partial_y & 0 & \partial_z & 0 & 0 \\
0 & 0 & \partial_z & 0 & \partial_x & 0
\end{pmatrix}
\]

(7)

and \( \mathbf{0}_6 \) denotes the zero matrix of dimension \( n \times n \). Moreover, \( \rho \) is the mass density. A numerical solution of Eq. (3) is obtained by means of a fourth-order Runge-Kutta method \([12]\).

A less straightforward issue using pseudospectral differential operators is to model the free-surface boundary condition. While in finite-element methods the implementation of traction-free boundary conditions is natural – simply do not impose any constraint at the surface nodes – finite-difference and pseudospectral methods require a particular boundary treatment \([23,14,25,26]\). Free-surface and solid–solid boundary conditions can be implemented in numerical modeling with the Chebyshev method by using a boundary treatment based on characteristics variables \([12]\). Most explicit time integration schemes compute the operation \( \mathbf{H} \cdot \mathbf{v} \equiv \langle \mathbf{v} \rangle^{\text{old}} \). The array \( \langle \mathbf{v} \rangle^{\text{old}} \) is then updated to give a new array \( \langle \mathbf{v} \rangle^{\text{new}} \) that takes the boundary conditions into account. Let us consider the boundary \( z = 0 \) (e.g., the surface) and let us assume that the wave is incident on this boundary from the half-space \( z > 0 \). The free surface conditions are obtained by computing the stresses from

\[
\sigma_{ij}^{(\text{new})} = \frac{b_1}{a_{14}} \sigma_{ij}^{(\text{old})} + \frac{b_2}{a_{25}} \sigma_{ij}^{(\text{old})} + \frac{b_3}{a_{37}} \sigma_{ij}^{(\text{old})},
\]

(8)

where

\[
\begin{pmatrix}
b_1 \\
b_2 \\
b_3
\end{pmatrix}
= \begin{pmatrix}
1 & 0 & 0 & 0 & 0 & 0 \\
0 & 1 & 0 & 0 & 0 & 0 \\
0 & 0 & 1 & 0 & 0 & 0
\end{pmatrix}
\begin{pmatrix}
a_{14} \\
a_{25} \\
a_{37}
\end{pmatrix},
\]

while the velocities are given by

\[
\begin{pmatrix}
v_x^{\text{new}} \\
v_y^{\text{new}} \\
v_z^{\text{new}}
\end{pmatrix} = \begin{pmatrix}
\tau_x \\
\tau_y \\
\tau_z
\end{pmatrix} + \mathbf{A}^{-1} \mathbf{B} \begin{pmatrix}
\sigma_{xx} \\
\sigma_{yy} \\
\sigma_{zz}
\end{pmatrix}^{(\text{old})},
\]

(9)

where

\[
\begin{pmatrix}
\tau_x \\
\tau_y \\
\tau_z
\end{pmatrix}
= \begin{pmatrix}
a_{41} & a_{42} & a_{43} \\
a_{51} & a_{52} & a_{53} \\
a_{61} & a_{62} & a_{63}
\end{pmatrix}
\begin{pmatrix}
\sigma_{xx} \\
\sigma_{yy} \\
\sigma_{zz}
\end{pmatrix}^{(\text{old})}
\]

and

\[
\begin{pmatrix}
\sigma_{xx} \\
\sigma_{yy} \\
\sigma_{zz}
\end{pmatrix}^{(\text{old})}
= \begin{pmatrix}
\sigma_{xx} \\
\sigma_{yy} \\
\sigma_{zz}
\end{pmatrix}^{(\text{old})}
\]
In the equations above, coefficients $a_{ij}$ depend only on the elastic coefficients and on density. Indeed, these coefficients may be computed based on the following three-step algorithm:

1. Define the matrix

$$C = \begin{pmatrix} 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & \rho^{-1} & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & \rho^{-1} & 0 \\ c_{15} & c_{14} & c_{13} & 0 & 0 & 0 & 0 & 0 \\ c_{25} & c_{24} & c_{23} & 0 & 0 & 0 & 0 & 0 \\ c_{35} & c_{34} & c_{33} & 0 & 0 & 0 & 0 & 0 \\ c_{56} & c_{46} & c_{36} & 0 & 0 & 0 & 0 & 0 \\ c_{55} & c_{45} & c_{35} & 0 & 0 & 0 & 0 & 0 \\ c_{45} & c_{44} & c_{34} & 0 & 0 & 0 & 0 & 0 \end{pmatrix}$$

2. Compute the matrix $Q$ whose columns are the eigenvectors of matrix $C$, and note that it has the form

$$Q = \begin{pmatrix} 0 & 0 & 0 & p_1 & -p_1 & q_1 & -q_1 & r_1 & -r_1 \\ 0 & 0 & 0 & p_2 & -p_2 & q_2 & -q_2 & r_2 & -r_2 \\ 0 & 0 & 0 & p_3 & -p_3 & q_3 & -q_3 & r_3 & -r_3 \\ 1 & 0 & 0 & p_4 & p_4 & q_4 & q_4 & r_4 & r_4 \\ 0 & 1 & 0 & p_5 & p_5 & q_5 & q_5 & r_5 & r_5 \\ 0 & 0 & 0 & p_6 & p_6 & q_6 & q_6 & r_6 & r_6 \\ 0 & 0 & 1 & p_7 & p_7 & q_7 & q_7 & r_7 & r_7 \\ 0 & 0 & 0 & p_8 & p_8 & q_8 & q_8 & r_8 & r_8 \end{pmatrix}$$

3. Compute the inverse of matrix $Q$, and note that it has the form

$$Q^{-1} = \begin{pmatrix} 0 & 0 & 0 & a_{16} & 0 & a_{18} & a_{19} \\ 0 & 0 & 0 & a_{41} & a_{42} & a_{43} \\ 0 & 0 & 0 & -a_{14} & -a_{12} & -a_{13} \\ 0 & 0 & 0 & a_{61} & a_{62} & a_{63} \\ 0 & 0 & 0 & -a_{81} & -a_{82} & -a_{83} \end{pmatrix}$$

The relationship between matrices (10) and (11) is given by

$$a_{16} = [p_3(q_4 r_4 - q_4 r_3) + p_4(q_4 r_5 - q_4 r_4) + p_4(q_5 r_8 - q_5 r_9)]/d_1,$$

$$a_{18} = [p_5(q_4 r_6 - q_4 r_5) + p_5(q_4 r_9 - q_4 r_8) + p_5(q_3 r_9 - q_3 r_8)]/d_1,$$

$$a_{19} = [p_5(q_4 r_7 - q_4 r_6) + p_5(q_4 r_6 - q_4 r_5) + p_5(q_4 r_7 - q_4 r_6)]/d_1,$$

$$a_{25} = [p_5(q_4 r_5 - q_4 r_3) + p_5(q_5 r_5 - q_5 r_3) + p_5(q_5 r_9 - q_5 r_8)]/d_1,$$

$$a_{29} = [p_5(q_4 r_7 - q_4 r_6) + p_5(q_4 r_6 - q_4 r_5) + p_5(q_4 r_7 - q_4 r_6)]/d_1,$$

$$a_{35} = [p_5(q_4 r_9 - q_4 r_6) + p_5(q_4 r_6 - q_4 r_5) + p_5(q_4 r_9 - q_4 r_6)]/d_1,$$

$$a_{39} = [p_5(q_4 r_7 - q_4 r_6) + p_5(q_4 r_6 - q_4 r_5) + p_5(q_4 r_7 - q_4 r_6)]/d_1.$$
Finally, the non-reflecting (i.e., absorbing) boundary conditions arise from the following system of equations for the particle velocities

\[
\begin{bmatrix}
  a_{41} & a_{42} & a_{43} \\
  a_{61} & a_{62} & a_{63} \\
  a_{81} & a_{82} & a_{83}
\end{bmatrix}
\begin{bmatrix}
  v_x^{\text{new}} \\
  v_y^{\text{new}} \\
  v_z^{\text{new}}
\end{bmatrix}
= \frac{1}{2}
\begin{bmatrix}
  b_5 \\
  b_7 \\
  b_9
\end{bmatrix},
\]

where

\[
d_1 = p_9(q_8r_8 - q_9r_7) + p_8(q_9r_9 - q_8r_8) + p_6(q_8r_9 - q_9r_8);
\]

\[
d_2 = 2[p_3(q_1r_2 - q_2r_1) + p_2(q_1r_1 - q_3r_3) + p_1(q_3r_3 - q_1r_2)].
\]

Finally, the non-reflecting (i.e., absorbing) boundary conditions arise from the following system of equations for the particle velocities together with

\[
\begin{bmatrix}
  a_{14} & a_{16} & a_{18} & a_{19} \\
  a_{25} & a_{26} & a_{28} & a_{29} \\
  a_{36} & a_{38} & a_{39} \\
  a_{46} & a_{48} & a_{49} \\
  a_{66} & a_{68} & a_{69} \\
  a_{86} & a_{88} & a_{89}
\end{bmatrix}
\begin{bmatrix}
  \sigma_{xx}^{\text{new}} \\
  \sigma_{yy} \\
  \sigma_{zz} \\
  \sigma_{xy} \\
  \sigma_{xz} \\
  \sigma_{yz}
\end{bmatrix}
= \begin{bmatrix}
  b_1 \\
  b_2 \\
  b_3/2 \\
  b_4/2 \\
  b_5/2 \\
  b_6/2
\end{bmatrix},
\]

where
3.2. The spectral-element method

In the spectral-element method (SEM), which is a continuous Galerkin approach, the strong form of the equations of motion (1) is first rewritten in a variational or weak formulation. Using such a variational approach has the direct advantage that the free-surface boundary condition at the surface of the model, which says that traction should be zero along the surface, is the natural boundary condition of the technique. Thus, one does not need to implement it explicitly, it is automatically enforced accurately. Because of that, the propagation of surface waves and their interaction with the shape of the surface of laboratory models can be computed in a very precise fashion [27]. This is true for geophysical models as well, for which the effect of complex topography on both surface waves and body waves can be accurately predicted [28].

The SEM being a full waveform modeling technique, it can compute terms that are often neglected in approximate methods, for instance the near-field terms [29]. Another advantage of that technique is that, contrary to finite-difference methods for instance, it does not need to resort to a staggered numerical grid in which different components of the strain tensor are defined at different locations; on the contrary, in the SEM all the components are defined at the same Gauss–Lobatto–Legendre grid point, and as a

\[
\begin{pmatrix}
\frac{b_5}{b_7} \\
\frac{b_9}{b_7}
\end{pmatrix}
= -A \begin{pmatrix}
\frac{u_y}{v_y}
\end{pmatrix}^{\text{(old)}} + B \begin{pmatrix}
\sigma_{zz}^{\text{(old)}} \\
\sigma_{xz}
\end{pmatrix},
\]

with A and B given in (9), while \(b_1, b_2\) and \(b_3\) are given by (8).

Fig. 4. Snapshots at propagation times of 28 µs, 34 µs, 40 µs and 46 µs computed using the spectral-element technique at the surface of a three-dimensional copper crystal, i.e., in the (x,y)-plane.
result the sum of all the strain terms required by Hooke’s law in the case of general anisotropic media (2) can be performed without any additional interpolation. As a result, the SEM is very well suited to studying elastic wave propagation in complex anisotropic media [30–32].

Another important property of the SEM is the fact that it can be parallelized efficiently to take advantage of the distributed structure of modern supercomputers [33], and in particular on clusters of Graphics Processing Units (GPU) graphics cards [34–36], reaching speedup factors of more than an order of magnitude compared to a reference serial implementation on a CPU core; this makes it compare well in terms of performance to less flexible algorithms such as finite differences in the time domain (FDTD), which can also be implemented efficiently on GPUs [37,38].

Writing the variational form of the elastic wave equation is accomplished by dotting the strong (i.e., differential) form of the equation with an arbitrary test vector $w$ and integrating by parts over the region of interest:

$$
\int_{\Omega} \rho \mathbf{u} \cdot \mathbf{d} \Omega + \int_{\Omega} \mathbf{v} : \mathbf{C} : \mathbf{u} d \Omega = \int_{\Omega} \mathbf{w} \cdot \mathbf{f} d \Omega + \int_{\Gamma_{\text{abs}}} \mathbf{w} \cdot \mathbf{t} d \Gamma, \tag{12}
$$

where $\mathbf{f}$ denotes the known external source force, $\mathbf{t}$ denotes the traction vector, and $\Omega$ denotes the domain under study, whose boundary $\Gamma$ usually consists in two parts: a boundary $\Gamma_{f}$ on which free-surface (i.e., traction-free) conditions are implemented, and an artificial boundary $\Gamma_{\text{abs}}$ used to truncate semi-infinite domains and on which outgoing waves must be absorbed. In the integration by part above, we have used the fact that the traction vanishes on the free boundaries $\Gamma_{f}$ of the domain and thus the related terms does not appear in the weak formulation because it is its natural boundary condition. In order to absorb outgoing waves on the fictitious edges of the mesh, Convolution Perfectly Matched absorbing Layers (C-PML) are implemented, see e.g. [39–41]; however in the case of elastic wave propagation in anisotropic crystals usually all the edges of the crystal are either free (‘Neumann’ boundary condition) or fixed/rigid with zero displacement (‘Dirichlet’ boundary condition) because the crystal is of finite size and thus no absorbing conditions need to be implemented.

To implement the Legendre spectral element discretization of the variational problem (12), one first needs to create a mesh of non-overlapping hexahedra $\omega_{e}$ on the domain $\Omega$, as in a classical finite element method (FEM). These elements are subsequently mapped to a reference cube $A = [-1,1]^3$ using an invertible local
mapping $\mathcal{F}: \Omega \rightarrow \Omega_0$, which enables one to go from the physical domain to the reference domain, and vice versa.

On the reference domain $\Omega_0$, one then defines a set of nodes and chooses the polynomial approximation $u_0^N$ and $w_0^N$ of $u$ and $w$ to be the Lagrange interpolant at this set of nodes. These nodes $\zeta_i \in [-1,1]$, $i = 0, \ldots, N$, are the Gauss–Lobatto–Legendre (GLL) points which are the $(N + 1)$ roots of

$$(1 - \zeta^2)P_N(\zeta) = 0,$$  

where $P_N(\zeta)$ is the derivative of the Legendre polynomial of degree $N$. On the reference domain $\Omega_0$, the restriction of a given function $u_N$ to the element $X_e$ can be expressed as

$$u_N^e(\zeta; \eta; \gamma) = \sum_{p=0}^{N} \sum_{q=0}^{N} \sum_{r=0}^{N} \sum_{i=0}^{N} \sum_{j=0}^{N} \sum_{k=0}^{N} u_N^{i,j,k}(\zeta_p, \eta_q, \gamma_r) h_p(\zeta) h_q(\eta) h_r(\gamma).$$  

where $h_p(\zeta)$ denotes the $p$th 1-D Lagrange interpolant.

After introducing the piecewise-polynomial approximation (14), the integrals in (12) can be approximated at the element level using the GLL integration rule:

$$\int_{\Omega_e} u_{\Omega_e} w_{\Omega_e} \, d\Omega = \sum_{p=0}^{N} \sum_{q=0}^{N} \sum_{r=0}^{N} \sum_{i=0}^{N} \sum_{j=0}^{N} \sum_{k=0}^{N} u_N^{i,j,k}(\zeta_p, \eta_q, \gamma_r) w_N^{i,j,k}(\zeta_p, \eta_q, \gamma_r) h_p(\zeta) h_q(\eta) h_r(\gamma).$$  

which will lead to a perfectly diagonal mass matrix.
The weights \( \omega_i > 0 \) are independent of the element and are determined numerically [42], and \( J_e \) is the Jacobian associated with the mapping \( \mathcal{F} \), from the element \( \Omega_e \) to the reference domain \( \Omega \).

Gradients are first computed in the reference domain \( \Omega \):

\[
\frac{\partial}{\partial x_j} u^e_i(x, \eta, \gamma) = \sum_{p=0}^N \sum_{q=0}^N \sum_{r=0}^N u^e_{ij}(\xi_p, \eta_q, \gamma_r) h^e_p(\xi) h^e_q(\eta) h^e_r(\gamma),
\]

\[
\frac{\partial}{\partial y_j} u^e_i(x, \eta, \gamma) = \sum_{p=0}^N \sum_{q=0}^N \sum_{r=0}^N u^e_{ij}(\xi_p, \eta_q, \gamma_r) h^e_p(\xi) h^e_q(\eta) h^e_r(\gamma),
\]

\[
\frac{\partial}{\partial z_j} u^e_i(x, \eta, \gamma) = \sum_{p=0}^N \sum_{q=0}^N \sum_{r=0}^N u^e_{ij}(\xi_p, \eta_q, \gamma_r) h^e_p(\xi) h^e_q(\eta) h^e_r(\gamma),
\]

where the components of the Jacobian matrix, \( \xi_0, \eta_0, \gamma_0 \) etc. are computed based upon the mapping \( \mathcal{F} \).

The effects of anisotropy in (12) are included in the term \( \int_{\Omega_e} \mathbf{v} \mathbf{w} \cdot \nabla^2 \mathbf{u} \), which can be rewritten as \( \int_{\Omega_e} \sigma(\mathbf{u}) : \mathbf{v} \mathbf{w} \),\( \text{d}\Omega \). Written out explicitly, the integrand is

\[
\sigma(\mathbf{u}) : \mathbf{v} \mathbf{w} = \sigma \delta_{ij} w_i w_j. \quad (19)
\]

In the fully anisotropic 3-D case, using the definition \( \varepsilon_{ij} = (\partial_{ij} u + \partial_{ji} u)/2 \), Hooke’s law (2), when injected in (19) to obtain the developed expression of \( \sigma(\mathbf{u}) : \mathbf{v} \mathbf{w} \), gives a sum of terms of the form \( c_{ijkl} \partial_{ij} u \partial_{kl} u \), with \( c_{ijkl} \) the components of the reduced stiffness matrix in (2). Each of these terms, integrated over an element \( \Omega_e \), is easily computed by substituting the expansion of the fields (14), computing gradients using (17) and the chain rule (18), and using the GLL integration rule (16).

After this spatial discretization with spectral elements, imposing that (12) holds for any test vector \( \mathbf{w}_e \), as in a classical FEM, we have to solve an ordinary differential equation in time. Denoting by \( \mathbf{u} \) the global vector of unknown displacement in the medium, we can rewrite Eq. (12) in matrix form as

\[
\ddot{\mathbf{u}} + \mathbf{K} \mathbf{u} = \mathbf{f}, \quad (20)
\]

where \( \mathbf{M} \) is called the mass matrix, \( \mathbf{K} \) the stiffness matrix, and \( \mathbf{f} \) the source term. A very important property of the Lagrange SEM used here from an implementation point of view, which allows for a drastic reduction in the complexity and the cost of the algorithm, is the fact that the mass matrix \( \mathbf{M} \) is diagonal; this stems from the choice of Lagrange interpolants at the GLL points in conjunction with the GLL integration rule, which results in (15). This constitutes a significant difference compared to a classical FEM and to the Chebyshev SEM of Patera [15] and of e.g. Priolo et al. [43]. As a result, fully explicit time evolution schemes can be used.

Time discretization of the second-order ordinary differential equation in time (20) is performed on a classical explicit Newmark centered finite-difference scheme [44], which is second-order accurate and conditionally stable. We assume zero initial conditions for the displacement and velocity fields, i.e., the medium is initially at rest. Higher-order time schemes can be used if needed, for instance fourth-order Runge-Kutta or symplectic schemes [45,46]; this can be useful in particular for simulations comprising a very large number of time steps, for which the fact that the spatial SEM discretisation is of high order while the time discretisation is only second order implies that overall accuracy is significantly reduced because of the time scheme.

4. Numerical simulations

We consider the materials whose properties are given in Table 1, and which are dissimilar: apatite, beryllium and zinc have hexagonal symmetry and copper has cubic symmetry, with \( c_{22} = c_{11} \), while epoxy is isotropic.

The pseudospectral method uses a mesh composed of 81 grid points along the three Cartesian directions, with a constant grid spacing of 2.5 mm along the x- and y-directions and a total mesh size of 20 cm in the z-direction with varying grid spacing. The surface of the sample is the \((x,y,z = 0)\)-plane. The source is a vertical force located at the surface and has the time history

\[
h(t) = \cos[2\pi(t - t_0)f_0] \exp \left[ -2(t - t_0)^2/f_0^2 \right], \quad (21)
\]

where \( f_0 \) is the dominant frequency and \( t_0 = 3/(2f_0) + 5.10^{-8} \) s is an onset delay time that we use in order to ensure zero initial conditions. The time step of the Runge-Kutta algorithm is 0.05 \( \mu \) s for apatite and 0.1 \( \mu \) s for zinc and copper. Figs. 1–3 show the wavefronts (energy velocities) in an unbounded medium and snapshots in the \((x,z)\)-plane for apatite, zinc and copper. The dominant frequencies

Fig. 9. Snapshot computed using the pseudospectral technique at the surface (a) and at a vertical section (b). The medium is zinc overlaid by a substrate of epoxy of 5 mm thickness.
of the source are 250 kHz, 150 kHz and 200 kHz, with total propagation times of 25 µs, 50 µs and 40 µs, respectively.

The Rayleigh wave can be observed at the surface, and the qP and qS waves in the interior of the medium. Fig. 4 shows spectral-element snapshots at different propagation times at the surface of copper, i.e., in the (001)-plane in terms of Miller indices, where the Rayleigh wavefront can be seen [47].

The mesh contains a total of 90 × 90 × 90 spectral elements and we use polynomial basis functions of degree $N = 4$. The total size of the mesh is 40 cm × 40 cm × 40 cm and we use a time step of 0.03 µs. Apatite and zinc are azimuthally isotropic in this surface and therefore the wavefront is isotropic. Snapshots for the pseudospectral method of the wave field at the surface of apatite, with the sample rotated by an angle of $\pi/4$ and then an angle of $\pi/2$ with respect to the surface are displayed in Fig. 5. The surfaces are the (101)- and (100)-planes in terms of Miller indices. In this case, the anisotropy of the Rayleigh wave can clearly be observed.

The analytical solution [48] for the three-dimensional Green's function (i.e., the impulse response) for a surface source and a receiver located along a vertical line below the source, in the interior of the medium, is represented in Fig. 6.

For completeness the analytical expression to compute it is given in Appendix A. It corresponds to the Green function computed 15 cm below the surface for apatite and then for beryllium. The P- and S-wave velocities of beryllium are almost twice that of other metals, i.e., 13,484 m/s and 9363 m/s along the symmetry axis, respectively. These high velocities allow us to use a larger grid spacing of 4.4 mm in the x- and y-directions for the pseudospectral technique and a total mesh size of 35 cm in the z-direction, keeping the same time step as that used for apatite, i.e., 0.05 µs; using a smaller grid allows us to save in terms of computational cost. Validation tests for both modeling algorithms versus the analytical solution convolved with the source time history (21) for apatite and beryllium are shown in Fig. 7. The fit obtained is excellent for both techniques.

In the case of the spectral-element method, the mesh contains a total of 60 × 60 × 60 spectral elements and we use polynomial basis functions of degree $N = 4$. The total size of the mesh is... 

![Fig. 10. Model made of epoxy and zinc (a) and corresponding surface waves (b) and snapshot computed using the pseudospectral technique at a vertical section (c).](image-url)
frequency of 200 kHz is applied at its center. Fig. 8 shows a snap- shot at a time of 36 μs for a copper crystal; the qP and qS waves can be seen (outer and inner wavefronts, respectively). When com- paring to Fig. 3a, one can observe that the ends of the qS cusps ex- tend as diffraction phenomena forming two quasi-ellipses.

Because the simulation is two dimensional and the source is placed in the center of the model, it contains no surface waves, only body waves. This explains why this snapshot looks different from the snapshots of Fig. 4, which are dominated by surface waves. Indeed, as the simulation illustrated in Fig. 4 is three dimensional with the source located exactly at the surface, Fig. 4 thus not only has body waves as in Fig. 3a, but also surface waves superimposed and dominant.

The proposed modeling algorithms can handle heterogeneous media, therefore numerical simulations can be performed in cases for which there is no known analytical solution. In the next simulation we consider a zinc sample coated with a substrate of epoxy of 5 mm thickness. Epoxy is isotropic and has the elastic constants given in Table 1. The simulation uses the same numerical parameters as those used to generate Fig. 2, but the vertical force source is located at a depth of 1 cm in the zinc crystal. In the snap- shots of Fig. 9, isotropic and dispersive Rayleigh wavefronts can be seen at the surface, and we notice that most of the energy is con- tained in the thin substrate.

The model shown in Fig. 10a is composed of a prism of epoxy embedded in zinc. The numerical parameters are unchanged and the source is a combination of three directional forces applied at the location indicated by a star in the model. Figs. 10b and c show snapshots at the surface and at vertical section at a time of 55 μs, respectively. Most of the energy is trapped in the epoxy prism.

Fig. 11 shows snapshots at a time of 50 μs at the same planes but replacing the epoxy prism with a copper prism. The impedance contrast between the two media is weaker and therefore energy trapping is much reduced.

5. Conclusions

The two numerical modeling methods compute the full wave field and have spectral accuracy. At each grid point these methods allow us to model an anisotropic medium of arbitrary crystal sym- metry, i.e., a triclinic medium or a medium of lower symmetry whose symmetry axes can be rotated by any angle. We have shown numerical examples for media of hexagonal or cubic symmetry, for which we obtained time histories and snapshots at the surface and at vertical sections. The wavefronts have been compared with the ray surfaces (energy or group velocities) obtained based on a plane-wave analysis. The modeling algorithms have been success- fully tested against the analytical solution for a point force source located at the surface of a crystal and a receiver located in the inte- rior of the medium. We have shown how these modeling tools can be used to simulate phenomena predicted by plane-wave analyses, as the continuation of the cuspidal triangles of the qS wave in cubic crystals. Moreover, we have simulated wave propagation in the presence of a free surface in cases where there is no analytical solu- tion for models composed of media of dissimilar crystal symmetry and with contrasting elastic properties.

Some of the calculations were performed on an SGI cluster at Centre Informatique National de l’Enseignement Supérieur (CINES) in Montpellier, France. This material is based in part upon research supported by European FP6 Marie Curie International Reintegra- tion Grant MIRG-CT-2005-017461.
Appendix A. Analytical solution for transversely isotropic media

We briefly summarize the main formulas used in this article to compute the analytical vertical motion in a VTI half-space with horizontal free surface. For a thorough treatment, see Payton [53,48].

A.1. Step response

Two cases are considered: (i) buried source with receiver at the epicenter (idealized earthquake), and (ii) source at the surface with receiver in its vertical (idealized geophysical exploration or laboratory experiment). The two problems are mathematically related through the reciprocity principle [54].

A.1.1. Buried source

When the time dependence of the source is described by Heaviside’s step function, the vertical displacement at the epicenter is given by

\[ u_z(t) = \frac{\rho f_z}{4\pi c_{44}^2 z_s} \left( \frac{\sqrt{c_{44}^2 \rho}}{z_s} \right) \tag{A.1} \]

where \( t \) is time, \( \rho \) is density, \( f_z \) is the amplitude of the vertical body force, \( c_{44}^2 \) is an elastic constant in Voigt notation, and \( z_s \) is the depth of the buried source. In (A.1), function \( u_0 \) depends on the type of material; for example, in the case of apatite, we have

\[ u_0(\theta) = \begin{cases} 0 & \text{if } 0 \leq \theta < \pi/2 \\ F(\omega) g(\theta) & \text{if } \pi/2 < \theta < \pi \\ 2F(\omega) g(\theta) & \text{if } 1 < \theta < T_+ \\ 2 \text{Re} \left\{ F(\omega) \left[ \frac{1}{2} + 1 - \frac{\omega^2}{2C_0^2} \right] \right\} & \text{if } T_+ \leq \theta < \infty \end{cases} \tag{A.2} \]

where

\[ F(\omega) = \frac{2\sqrt{\omega}}{f - \theta d} \tag{A.3} \]

with

\[ f(\omega) = \sqrt{\frac{\omega + 2 + 2\omega^2}{\omega}} \]

\[ V(\omega) = \frac{1}{\omega}\left[(1 - \kappa)\omega(\omega + 1) - \frac{1}{\kappa}\left[(\kappa - 1)(\omega + 1) + 2\omega(\omega + 1) + \frac{1}{\kappa}\right]ight] \]

\[ d(\omega) = 2(1 - \kappa)\omega(\omega + 1) - (\omega \omega + x)(\omega + 1) - 2\omega f. \tag{A.4} \]

In (A.2)-(A.4), we have defined

\[ \omega = \zeta(\theta) + iv(\theta), \]

where

\[ \zeta(\theta) = \frac{1}{2\beta} \left[ \omega^2 - (\beta + 1) \right], \tag{A.5} \]

\[ v(\theta) = \frac{1}{2\beta} \sqrt{(4\beta^2 - \chi^2)(\omega^2 - T_+^2)}, \]

and

\[ T_+^2 = -\frac{\beta(\beta + 1) + \chi(1 + \beta \beta - \chi)}{4\beta^2 - \chi^2}. \tag{A.6} \]

Parameters \( \alpha, \beta, \chi, \kappa \) appearing in (A.2)-(A.6) represent non-dimensional elastic constants defined by

\[ \alpha = \frac{c_{33}}{c_{44}}, \quad \beta = \frac{c_{11}}{c_{44}}, \quad \chi = 1 + \frac{c_{11}}{c_{44}^2 + 1}, \quad \kappa = \sqrt{1 + \alpha \beta - \chi} \]

where \( c_{ij} \) are, as usual, the anisotropic elastic constants in the abbreviated Voigt notation. In (A.2), \( g \) and \( \omega_3 \) are defined as

\[ g(\theta) = \frac{1}{2} \left( \frac{2 - \chi}{2\beta} + \beta - 1 \right), \]

\[ \omega_3 = \frac{\chi \omega^2 - (\beta + 1) + S(\theta)}{2\beta} \]

where

\[ S(\theta) = \sqrt{[\chi(\omega^2 - (\beta + 1))^2 - 4\beta(\omega^2 - 1)(\omega^2 - 1)]. \]

Finally, function \( Q(\theta) \) appearing in (A.2) is given by

\[ Q(\theta) = \frac{\sqrt{4\beta(\omega^2 - 1)(\omega^2 - 1) - \chi(\omega^2 - (\beta + 1)^2)}}{\omega_3}. \tag{A.7} \]

A.1.2. Response to an arbitrary wavelet

The epicentral-axis displacement generated at \((0,0,0)\) by a vertical point load located at \((0,0,0)\) on the horizontal free surface is given by

\[ u_0(x = 0, y = 0, z, t) = 0, \]

\[ u_0(x = 0, y = 0, z, t) = 0, \]

\[ u_0(x = 0, y = 0, z, t) = \frac{h}{4\pi c_{44}^2} u_0 \left( \frac{T}{T} \right). \tag{A.8} \]

where \( h \) is the strength of the source, \( u_0 \) is given by (A.2), and

\[ T = \sqrt{\frac{c_{44}^2}{\rho}}. \]

A.2. Response to an arbitrary wavelet

For convenience, we denote here with \( u_0 \) any one of the displacements (A.1) or (A.7), which are due to a source whose time dependence is described by the step function \( \delta \). Likewise, let \( u_\delta \) be the displacement due to an arbitrary wavelet \( \phi(t) \). Since the relationship between \( \phi \) and \( u_\delta \) is linear and time invariant, there exists a function \( G \) such that

\[ u_\delta = G \ast \phi. \tag{A.9} \]

where the asterisk denotes time convolution. Putting \( \psi = \delta \) in (A.8) yields \( G = u_0 \) and hence

\[ u_\psi = u_\delta \ast \phi, \] (A.10)

from which, in particular, we get

\[ u_\psi = u_\delta \ast \theta. \tag{A.11} \]

Thus, given any point source, the vertical displacement and velocity can be computed from the step-response displacement by using

\[ u_\delta = u_\delta \frac{d\phi}{dt}, \tag{A.11} \]

\[ V_\phi = u_\delta \frac{d^2\phi}{dt^2}. \]
